(54) Title: ELECTRICAL DEVICE

(57) Abstract

An electrical device comprises a body of a switching material (3, 13, 24) and a pair of electrodes (1, 4; 11, 14 et 15; 22, 23) that are located on the switching material with at least part of the switching material between them. The switching material preferably comprises an amorphous silicon compound that has been formed by reacting amorphous silicon or a compound thereof with a passivating agent to remove or reduce the number of unpaired electrons occurring therein. The device exhibits a voltage controlled negative resistance (VCNR) which may be employed for example for transient protection; and also has relatively constant electrical properties over a long period of time.

ELECTRICAL DEVICE

This invention relates to electrical devices, and in particular to electrical switching devices.

A number of devices have been proposed in the art for switching between high and low resistance states. For example chalcogenide glass switches have been proposed in our co-pending European patent application EP-A-0,196,891. In addition silicon-containing switches have also been proposed. An amorphous silicon structure that switches from a low resistance to a high resistance state on application of an electrical potential above a given value is described for example by L. Mei and J.E. Greene, J. Appl. Phys Suppt. 2 Pt 1 (1974). However such a structure has the disadvantage that the ratio of the resistivity of the device in its high resistance state to that in its low resistance state is only 7:1, with the result that it would not be possible to form a useful switch for many purposes from such a material.

- 2 -

According to the present invention there is provided an electrical device, which comprises a body of a switching material and a pair of electrodes that are located on the switching material with at least part of the switching material between them, the switching material comprising an amorphous silicon compound that has been formed by reacting amorphous silicon or a compound thereof with a passivating agent to remove or reduce the number of unpaired electrons occurring therein.

The device according to the invention has the advantage that the electrical resistance of its high resistance state (or off state) is considerably increased with respect to the resistance of its low resistance state (or on state), with the result that the device may be employed for example as an electrical switch or an electrical fuse that will act as an electrical conductor but will switch to a high resistance state when it is subjected to an overvoltage or over-current. The device according to the invention has been observed to act as a threshold device, that is to say, it will change from a low resistance state to a high resistance state when subjected to a current or voltage above a given value, referred to as the threshold current or threshold voltage, but will remain in its high resistance state only for as long as the applied voltage is greater than a defined minimum value referred to as the holding voltage.

The switching material is preferably formed by reacting amorphous silicon, or an amorphous silicon compound e.g. amorphous silicon carbide, amorphous silicon nitride or amorphous silicon oxide, with the passivating agent, amorphous silicon preferably being employed.

- 3 -

The device may be manufactured by a process comprising:

- (a) reacting an amorphous silicon or silicon compound with a passivating agent in order to remove or reduce the number of unpaired electrons occurring in the silicon compound;
- (b) providing a first electrode in association with the amorphous silicon compound either before or after step (a); and
- (c) providing a second electrode in association with the amorphous silicon compound either before or after step (a).

The body of switching material will usually be in the form of a layer, in which case the electrodes may be located on opposite sides of the layer so that electrical current will pass through the layer. This may be achieved by a process in which steps (a) and (b) are conducted simultaneously by depositing a layer of the silicon or silicon compound on the first electrode in the presence of the passivating agent, followed by step (c). This form of device may instead be formed by depositing a layer of amorphous silicon or silicon compound on the first electrode followed by incorporating the passivating agent therein as explained below, and provision of the second electrode.

Alternatively both electrodes may be located on the same side of the layer of switching material so that electrical current will flow along one surface, or at least parallel to the surface, of the layer. This may be achieved by a process in which steps (b) and (c) are conducted simultaneously. The electrodes may be provided after the silicon or silicon compound layer

- 4 -

has been formed or passivated, or the silicon or silicon compound layer may be deposited on the electrodes, reaction with the passivating agent being conducted simultaneously or subsequently as described elsewhere. A significant advantage of devices having both electrodes on the same side of the switching layer is that it is relatively easy to alter the electrode-electrode separation without affecting other manufacturing parameters such as the deposition time. It is possible by this means to have electrodes that are relatively widely spaced apart with the result that the off state resistance of the device is considerably increased. In addition the capacitance of the device will be significantly reduced and can be reduced yet further by appropriate choice of electrode configuration.

Although it is possible in all cases to passivate the silicon or silicon compound layer after deposition e.g. by means of a hydrogen plasma or by ion implantation, it is much preferred to passivate the silicon or silicon compound in step (a) simultaneously with deposition of the silicon or silicon compound.

The layer of switching material will normally be formed by a vapour deposition process, e.g. by evaporation, by chemical vapour deposition, plasma deposition or a sputtering process, in which cases the passivating agent may be present in the deposition atmosphere to react with the silicon or silicon compound being deposited. The passivating agent preferably comprises hydrogen or a halogen, more preferably hydrogen or fluorine, and especially hydrogen. In the case of plasma deposition, in which silane or a mixture of silane and a co-reactant e.g. ammonia (for silicon nitride) is employed as the vapour, the hydrogen passivating agent may be formed in situ by decomposition of the silane. Preferably 1 to 25, more preferably 5 to

- 5 -

15 atomic percent hydrogen may be incorporated in the silicon based film in order to remove the so-called "dangling bonds", the term "dangling bonds" as used herein simply being intended to mean unpaired electrons in the silicon atom valence orbitals. The degree to which the silicon atom "dangling bonds" are passivated will depend on the deposition conditions including the deposition pressure, these being chosen so that the number of dangling bonds in the amorphous silicon or silicon compound material is reduced from an original value of about $10^{20} \text{ eV}^{-1} \text{ cm}^{-3}$ to 10^{15} to $10^{17} \text{ eV}^{-1} \text{ cm}^{-3}$. The reduction in the dangling bond density due to passivation will relieve mechanical stress in the rigid tetrahedral structure and will sharply decrease the density of localized states thus decreasing the material's room temperature conductivity by many orders of magnitude. Normally the switching material will have resistivity in the range of 10^9 to 10^{11} ohm cm .

The silicon/hydrogen compound layer may advantageously be formed by depositing silicon by plasma deposition from a silane atmosphere. The silane is fed into a vacuum chamber maintained at a pressure of about 0.1 Torr, and passed between a pair of electrodes one of which may be earthed and the other of which self biases to a high negative potential due to the application of a radio frequency (13.56 MHz) signal. The substrate is located on one of these electrodes (usually the earthed electrode) and the material is deposited on the substrate in its amorphous state. Normally the deposition rate is not greater than 1 $\mu\text{m/hr}$, preferably not more than 0.2 $\mu\text{m/hr}$, preferably not more than 0.1 $\mu\text{m/hr}$, and at an elevated temperature, preferably from 100 to 400°C and especially from 200 to 300°C. If the layer is deposited too rapidly and/or at too low a temperature or too high a pressure, there is a danger that the hydrogen bonding

- 6 -

will be incorrectly configured. Silicon-hydrogen alloys, in contrast to pure amorphous silicon, have much smaller unpaired spin densities and exhibit predominantly band-like conduction rather than variable range hopping conduction among localized states. In addition to changing the conductivity of the layer the silicon hydrogen bond formation allows efficient n or p type doping which is not possible in either evaporated or sputtered pure amorphous silicon.

Alternatively, the materials may be deposited by a sputtering method. In this method predominantly neutral atomic or molecular species are ejected from a target, which may be formed from the material to be deposited, under the bombardment of inert positive ions e.g. argon ions. The high energy species ejected will travel considerable distances to be deposited on the substrate held in a medium vacuum e.g. 10^{-4} to 10^{-2} mbar. The positive ions required for bombardment may be generated in a glow discharge where the sputtering target serves as the cathode electrode to the glow discharge system. The negative potential (with respect to ground and the glow discharge is maintained in the case of insulating target materials by the use of radio frequency power applied to the cathode, which maintains the target surface at a negative potential throughout the process. DC power may be applied when the target is an electrically conducting material.

In some instances it may be appropriate to employ a reactive bias sputtering method in which reactive gas is introduced into the vacuum chamber in addition to argon so that the oxide or nitride of the target material, which in this case is silicon rather than silicon oxide or nitride, will be deposited. This method may be employed to incorporate the passivating agent in the silicon or silicon compound layer by

- 7 -

introducing the appropriate passivating agent gas. The compound forming the insulating layer may be stoichiometric or non-stoichiometric, the particular stoichiometry that is desired being determined inter alia by the quantity of the reactive gas in the vacuum chamber. The partial pressure of reactive gas will normally be between 2 and 30%, preferably up to 25%. As with plasma deposition, and for the same reason, the material is preferably deposited at a rate of not more than 1 micrometre per hour, most preferably not more than 0.2 micrometres per hour and especially about 0.1 micrometre per hour.

After deposition of the amorphous silicon layer, a metallic electrode, e.g. a silver, gold, nickel, molybdenum or chromium electrode is deposited on the switching layer, for example by evaporation e.g. by electron beam evaporation.

After deposition of the second electrode this form of device will exhibit a relatively high electrical resistance, at least up to voltages in the range of 5 to 30 V above which the current increases rapidly with increasing voltage, the particular value of the voltage depending among other things, on the thickness of the layer. After production of the device, it is normally subjected to a so-called "forming" operation in which at least part of the amorphous silicon compound layer is locally restructured by applying a high voltage across the electrodes. It is believed that the forming step causes a disc-like area of crystalline elemental silicon to be formed in the amorphous silicon. The increased temperatures associated with the forming operation cause decomposition e.g. dehydrogenation of any silicon compound to form elemental silicon in the disk-like area together with loss of that part of the electrode that overlies the disc-like area. A small filament is formed through the thickness of the device.

Once the device has been "formed" in this way, it exhibits a voltage controlled negative resistance (VCNR) effect in which it exhibits a low resistance until subjected to a high current or voltage as mentioned above. In contrast with the device described in the prior art, the devices according to the invention can have a ratio of off-state to on-state resistance of at least 50 and preferably at least 100. Devices having an off-state to on-state resistance ratio in the order of 500 and 1000 have been made. The properties exhibited by the devices such as off and on state resistance, threshold voltage etc have been observed to be relatively constant over a large number (5000) transients.

A number of theories have been proposed for the mechanism of the VCNR effect, and are described in Electrical Phenomenon in Amorphous Oxide Films, G. Dearnaley, A.M. Stoneham, D.V. Morgan, Rep. Prog. Phys. (1970), 33 1129-1192. In one such theory, the formed filament is reversably interrupted by current flow through it. In another theory, not mentioned in that reference, the forming of the device generates a conductive crystalline region or filament through the layer, and, as the electric field across the switching layer is increased, the emission of trapped electrons in the amorphous regions increases considerably by the Poole-Frenkel effect, with the result that electrons are drawn out of the conductive, crystalline regions into the considerably larger amorphous regions of the layer (which now has a large proportion of empty electron traps). The reduction of the number of electrons in the conductive crystalline region leads to an increase in the electrical resistance of the filaments which increases yet further with an increase in the applied electric field. In the device according to the invention the VCNR effect may occur through any of

- 9 -

these mechanisms or other mechanisms, but us normally associated with local dehydrogenation of the amorphous silicon hydrogen compound, and crystallisation depending on the local forming temperature.

It is believed that the low resistance of the device at low applied voltages is due to ohmic heating of the crystalline silicon region, the crystalline region having a large negative temperature coefficient of electrical resistance (NTC). At higher applied voltages the abrupt reduction in current flowing through the device is associated with thermionic and/or field effect emission of electrons from the crystalline regions, into regions having lower electron mobilities. Thus, according to another aspect, the invention provides an electrical device which comprises a body of an electrically insulating material and a pair of electrodes that are located on the insulating material with at least part of the insulating material between them, the device including at least one region of relatively electrically conducting material (in relation to the insulating material) that is located in the insulating material between the electrodes, the relatively conducting material having a negative temperature coefficient of electrical resistance (NTC) so that it will heat up due to ohmic heating when a voltage is applied to the device and will emit electrons into surrounding areas, at least at an applied field strength above a threshold value. Preferably at least one of the electrodes has a hole in the region of, and especially co-substantially coextensive with the region of relatively conducting material. Such a device has the advantage that the relatively conducting material can heat up more quickly under an applied voltage. The relatively conducting material preferably has a coefficient of electrical resistance below (i.e. having a greater negative value than) -1% , preferably below -2% and especially below -4% K^{-1} .

- 10 -

One problem that is associated with the forming operation used in the present invention is that a relatively high voltage (5 to 30 V) must be applied in order to allow sufficient current to be passed through the device to form it. This has the result that, when the resistance of the silicon layer suddenly decreases, a considerable amount of energy is put into the device. This method of forming is associated with relatively poor devices that have maximum current capacities of 1 uA or so. Preferably a layer or area of an n- or p-doped material is provided between the silicon compound layer and one or both of the electrodes. Thus, according to a preferred aspect, the invention provides an electrical device, which comprises a body of a switching material comprising an amorphous silicon compound, and a pair of electrodes that are located on the switching material and separated by it, and a region of an n- or p-doped silicon compound located between the switching material and at least one of the electrodes.

The provision of the n- or p-doped region has the advantage that the forming current can be applied at a much lower voltage e.g. about 1V, thereby reducing the energy put into the device during forming. Also, the n- or p-doped region may have a relatively small size, e.g., up to 10^{-8} m² and especially not more than 5×10^{-9} m², thereby concentrating the current density into a localized area and allowing forming to occur at lower currents e.g. not more than 400 mA, more preferably not more than 200 and especially not more than 100 mA. Thus the total forming energy can be reduced considerably with consequent reduction in damage to the device, producing devices with more appropriate characteristics such as increased current capacity.

Preferably the switching layer is as described above. Although it is quite possible for the base

- 11 -

material (i.e. un-doped) of the n- or p-doped layer to be different from that of the switching layer, it is preferred for them to be the same in which case the n- or p-doped layer can simply be formed by introducing a small quantity of dopant or precursor thereof into the deposition atmosphere during part only of the deposition process. Thus, for example, a small quantity, e.g. 0.1 to 5 volume percent, of phosphine or arsine (or, for p-type doping, diborane or boron trifluoride) may be incorporated into the silane at the start or at the end of the switching material deposition step. The doped layer may extend over the entire area of the device but preferably extends over part only of the device as described above, the remaining areas being masked during the deposition process.

The device according to the invention may be manufactured in any convenient shape or configuration and may be employed as a slow or fast fuse or for electrical transient suppression for example for suppression of transients due to lightning, electrostatic discharge, nuclear electromagnetic pulse and the like. The devices may be manufactured as individual devices, or as pairs of devices or as arrays with more than two devices in each array. For example one common electrode may be provided on one side of the switching layer, and a number of smaller separate electrodes may be provided on the opposite side of the switching layer.

The device according to the invention may be employed alone for protecting an electrical circuit, or it may be employed with one or more additional circuit protection devices, especially a circuit protection device whose impedance reduces when it is subjected to a transient. Such an additional device may for example clamp at a given voltage or may be a so-called

- 12 -

"foldback" device that changes from a high resistance state having a typical resistance of 1 Mohm, to a low resistance state of typical resistance 1 to 10 ohms, and may be connected in parallel with the load, with the fuse device according to the invention between them so that the additional device will shunt the transient across the load and, if necessary, protect the device according to the present invention from any over-voltage. Such additional device may comprise a conventional circuit protection device, for example a gas discharge tube, a varistor, Zener diode, a chalcogenide glass device for example as described in our copending European patent applications Nos. 196,891, 261,937, 261,938 and 261,939, or it may comprise a MIM device as described in our copending European application Nos. entitled "Electrical Circuit Protection Arrangement" or a "nin" device described in our copending European application entitled "Circuit Protection Arrangement", both applications filed on even date herewith and claiming priority from British applications Nos. 8816630.1 and 8816631.9. Any two or more of such additional devices may be used in combination with the device according to the invention depending on the circuit characteristics and the expected threat.

It is possible to form the MIM device according to our copending application and the fuse device according to the present invention from the same electrically insulating material, e.g. from an amorphous silicon-passivating agent compound, but in which the device according to the present invention has been subjected to a "forming" operation in which a large current is caused to flow through the insulating material. Thus, both devices may be formed as a single monolithic device, for example as part of a hybrid circuit, by depositing an appropriate design of electrically conducting tracks on a layer of the insulating material,

- 13 -

and the resettable fuse device may be "formed" by applying a potential difference across part only of the insulating material, e.g. by means of probes.

Several forms of device will now be described by way of example with reference to the accompanying drawings in which:

Figure 1 is a schematic cross-section through one form of device according to the invention;

Figure 2 is a schematic cross-section through another form of device;

Figure 3 is a schematic cross-section through yet another form of device;

Figure 4 is a schematic cross-section through a further form of device;

Figure 5 is a circuit diagram of a forming and test circuit for the device;

Figure 6 is a current/voltage curve obtained from a device according to the invention; and

Figure 7 is a schematic section through yet a further form of device;

Referring to the accompanying drawings, Figure 1 shows a device according to the invention in its simplest form. The device comprises a silver electrode 1 that has been on a conductive base 2, followed by a 300 nm thick layer 3 of intrinsic amorphous silicon that has been reacted with hydrogen to increase the electrical resistance of the silicon to a value of about 10^{10} ohm cm. A second silver electrode 4 is pro-

- 14 -

vided on the silicon/hydrogen compound layer 3, and a conductor, e.g. a gold wire 5, is bonded to the second electrode.

Figure 2 shows an alternative form of device in which a 100 nm thick silver electrode 11 is formed on a ceramic base 12 by evaporation followed by a 300 nm thick layer 13 of an intrinsic amorphous silicon/-hydrogen compound and two smaller 100 nm thick silver electrodes 14 and 15. Gold wire connections 16 may be formed on the top silver electrodes in known manner.

The silicon/hydrogen compound layer is formed by depositing silicon by plasma deposition from a silane atmosphere for example under conditions described below.

After deposition of the silicon/hydrogen layer a pair of silver electrodes 14 and 15 are deposited by evaporation. The silicon/hydrogen compound layer of the device shown in Figure 2 typically has an area in the range of from 1 to 10 mm² and the device has a total thickness in the range of from 300 to 500 um.

After fabrication the device must undergo a forming procedure before the VCNR effect can be observed. The devices can be electrically formed and tested using a Tektronix 370 Programmable Curve Tracer. The system configuration is shown in Figure 5.

The series resistance R_s (which also acts as a current measuring resistor) can be varied by discrete intervals between a maximum of .12 Mohms with a minimum of 0.36 ohm. During forming high R_s values are chosen and systematically reduced until a sharp change in the device resistance (from high to low) is observed. After this forming step a low R_s (typically 0.36 ohm)

- 15 -

is selected for device characterization. The wave forms are digitally acquired at a resolution of 100 points/division on both axes. An averaging facility is available (4 or 32 times) if required to reduce uncorrelated noise and to improve signal-to-noise ratio. A typical unaveraged characteristic is shown in Figure 5. This shows a device with R_{on} 30 ohms, R_{off} 7 kohms with a bipolar current threshold of 35 mA. The devices always reset to the on condition and reside in this condition until the current threshold is exceeded.

Figure 3 shows yet another form of device. This device has the same general construction as that shown in Figure 2 with the exception that an additional 50 nm thick layer 16 and 17 of n-doped amorphous silicon hydride is located between the layer 13 and each of the electrodes 14 and 15.

The n-doped layers are formed by introducing 1% phosphine into the silane atmosphere used for the production of the main switching layer 13, and masking the layer 13 to delimit the extent of the layers 16 and 17. The top electrodes are then deposited as described with respect to Figure 2.

Figure 4 shows a further form of device according to the invention in which a switching layer 20 has been deposited on a glass or ceramic substrate 21 by plasma deposition from a silane atmosphere as described above. After formation of the layer 20 a pair of electrodes 22 and 23 are deposited on the upper surface 24 of the layer 21 by evaporation. The device is then subjected to the forming operation as described above in order to cause local alteration of the atomic structure of the layer along its surface 24 between the electrodes.

- 16 -

Figure 7 is a schematic section through yet a further form of device in which a lower electrode 71 formed for example from copper or chromium is deposited on a glass body 70 followed by a layer 72 intrinsically semiconducting amorphous silicon so that some of the lower electrode remains exposed and that a region of the semiconducting layer 72 is deposited directly on the glass body 70. A small area 73 of n- or p-doped silicon is then formed in the intrinsically semiconducting layer 72 above the lower electrode, followed by the formation of the electrode 74. The upper electrode 74 extends over the amorphous silicon layer 72 and the n- or p-doped area 73 so that part of the upper electrode overlies the lower electrode 71 and part does not. The exposed part of the lower electrode 71 and the part of the upper electrode not overlying the lower electrode may be used for forming electrical connections, e.g., wire bonds 75 and 76 as shown or as pads for the test probes, without affecting the electrical properties of the device.

The following Examples illustrate the invention:

Example 1

A device having the general structure as shown in Figure 3 but having a single top electrode 14, was prepared by evaporating a 100 nm thick silver electrode 11 onto a glass substrate 12, followed by a 300 nm thick amorphous silicon-hydrogen layer 13. The layer 13 was deposited by plasma deposition at a substrate temperature of 270°C, a pressure of 0.1 Torr and a power of 0.2 W cm⁻², giving a deposition rate of 0.1 nms⁻¹. The deposition atmosphere used was 30% by volume silane 70% by volume helium.

After production of the layer 13, a 50 nm thick, 0.75 mm diameter layer 17 of n-doped silicon was depo-

- 17 -

sited in the same manner as layer 13 but with the addition of 1% phosphine, based on the volume of silane in the deposition feed gas. A 1 mm diameter 100 nm thick layer of silver was then deposited by evaporation.

The device was tested using the circuit shown in Figure 5 under the conditions shown below, and, after forming, exhibited a current-voltage trace of the general shape shown in Figure 6 with the properties given below.

Forming Conditions/Device Properties

forming current	I	1-10 mA
threshold voltage	V_{max}	1 V
threshold current	I_{max}	50 mA
	R_{on}	10 ohms
	R_{off}	10 k ohms
	R_{off}/R_{on}	1000
holding voltage	V_{on}	2-5 V

Example 2

Example 1 was repeated with the exception that the electrodes 11 and 14 were formed from evaporated nickel (100 nm thick). The forming conditions and properties of the resulting device were as follows:

Forming Conditions/Device Properties

Forming current I	100 mA
threshold voltage V_{\max}	1 V
threshold current I_{\max}	2 mA
R_{on}	250 ohms
R_{off}	26 k ohms
$R_{\text{off}}/R_{\text{on}}$	100
holding voltage V_{on}	2 V

EXAMPLE 3

A device of the general form shown in figure 7 was formed by evaporating a chromium layer 71 of 200 nm thickness followed by an amorphous silicon layer 72 of 200 nm thickness and a top electrode 74 comprising 50 nm silver and 150 nm gold. Before depositing the amorphous silicon layer a region of n^+ doped silicon 73 having a diameter of 50 to 100 nm and a thickness of 25 nm was formed by depositing amorphous silicon and then delimiting its size photolithographically. The device was formed using a 500 mA forming current and a forming voltage of 16 to 25V. The device had a current/voltage curve as shown in figure 8 with the following properties:

V_{\max}	2-4 V
I_{\max}	30-50 mA
R_{on}	50-70 ohms
R_{off}	5-10 k ohms
$R_{\text{off}}/R_{\text{on}}$	100-140

CLAIMS:

1. An electrical device, which comprises a body of a switching material and a pair of electrodes that are located on the switching material with at least part of the switching material between them, the switching material comprising an amorphous silicon compound that has been formed by reacting amorphous silicon or a compound thereof with a passivating agent to remove or reduce the number of unpaired electrons occurring therein.
2. A device as claimed in claim 1, wherein the switching material has been formed by reacting amorphous silicon, silicon carbide, silicon nitride or silicon oxide with the passivating agent.
3. A device as claimed in claim 1 or claim 2, wherein the switching material has been formed by reacting amorphous silicon with the passivating agent.
4. A device as claimed in any one of claims 1 to 3, wherein the passivating agent comprises hydrogen or a halogen.
5. A device as claimed in claim 4, wherein the passivating agent comprises hydrogen.
6. A device as claimed in any one of claims 1 to 5, wherein the switching material comprises from 1 to 30% by mole passivating agent.
7. A device as claimed in any one of claims 1 to 6, wherein the switching material has an unpaired electron density in the range of from 10^{15} to 10^{17} $\text{eV}^{-1} \text{cm}^{-3}$.

- 20 -

8. A device as claimed in any one of claims 1 to 7, which has been subjected to a forming operation in which localized atomic restructuring occurs in the switching material.
9. An electrical device which comprises a body of an electrically insulating material and a pair of electrodes that are located on the insulating material with at least part of the insulating material between them, the device including at least one region of relatively electrically conducting material (in relation to the insulating material) that is located in the insulating material between the electrodes, the relatively conducting material having a negative temperature coefficient of electrical resistance (NTC) so that it will heat up due to ohmic heating when a voltage is applied to the device and will emit electrons unto surrounding areas, at least at an applied field strength above a threshold value.
10. A device as claimed in claim 9, which at least one of the electrodes has a hole in the region of the relatively conducting material.
11. A device as claimed in any one of claims 1 to 10 wherein the electrodes are formed from silver, gold, nickel, molybdenum or chromium or crystalline silicon.
12. A device as claimed in any one of claims 1 to 11, which includes an n- or p-doped amorphous silicon compound layer between the switching material and one of the electrodes.
13. An electrical device, which comprises a body of a switching material comprising an amorphous silicon compound, and a pair of electrodes that are located on the switching material and separated by it, and a

- 21 -

region of an n- or p-doped silicon compound located between the switching material and at least one of the electrodes.

14. A device as claimed in claim 12 or claim 13, wherein the n- or p-doped silicon compound comprises, apart from its dopant, substantially the same material as the switching material.

15. A device as claimed in any one of claims 12 to 14, wherein the layer of n- or p-doped compound does not extend over the whole continuous area of the electrode and switching material.

16. A device as claimed in any one of claims 1 to 15, wherein the body of switching material is in the form of a layer and the electrodes are located on opposite sides of the layer.

17. A device as claimed in any one of claims 1 to 15, wherein the body of switching material is in the form of a layer and the electrodes are both located on the same side of the layer.

18. A method of producing an electrical device, which comprises:

- (a) reacting an amorphous silicon or silicon compound with a passivating agent in order to remove or reduce the number of unpaired electrons occurring in the silicon compound;
- (b) providing a first electrode in association with the amorphous silicon compound either before or after step (a); and
- (c) providing a second electrode in association with the amorphous silicon compound either before or

- 22 -

after step (a).

19. A method as claimed in claim 18, wherein steps (a) and (b) are conducted simultaneously by depositing a layer of the silicon or silicon compound on the first electrode in the presence of the passivating agent, followed by step (c) so that the electrodes are located on opposite sides of the layer.
20. A method as claimed in claim 18, wherein steps (b) and (c) are conducted simultaneously so that both electrodes are located on the same side of the amorphous silicon compound.
21. A method as claimed in claim 20, wherein steps (b) and (c) are conducted after step (a).
22. A method as claimed in any one of claims 18 to 21, wherein the amorphous layer is deposited by plasma deposition or reactive sputtering.
23. A method as claimed in any one of claims 18 to 22, which includes a "forming" step in which at least part of the amorphous silicon compound layer is restructured by passing an electric current through the device.
24. A method as claimed in claim 23, wherein the forming step is conducted under conditions that limit the maximum current passing through the device to 200 mA.
25. A method as claimed in claim 24, wherein the maximum current is limited by means of a current limiting resistor.
26. A method as claimed in claim 24 or claim 25, which includes the formation of an n- or p-doped

- 23 -

amorphous silicon compound layer adjacent to one of the electrodes.

27. A method as claimed in claim 26, wherein the n-doped amorphous silicon compound layer is formed by introducing an n- or p-dopant into the reactant during part only of the deposition step.

28. A method as claimed in any one of claims 18 to 26, wherein the passivating agent comprises hydrogen or a halogen.

29. A method as claimed in claim 28, wherein the dopant comprises phosphine, arsine, diborane or boron trifluoride.

ANNEX TO THE INTERNATIONAL SEARCH REPORT
ON INTERNATIONAL PATENT APPLICATION NO.

GB 8900797
SA 30106

This annex lists the patent family members relating to the patent documents cited in the above-mentioned international search report.
The members are as contained in the European Patent Office EDP file on 24/11/89
The European Patent Office is in no way liable for these particulars which are merely given for the purpose of information.

Patent document cited in search report	Publication date	Patent family member(s)	Publication date
